ABSTRACT

Multicasting can be an effective routing service in wireless mesh networks (WMNs), which have gained significant acceptance in recent years due to its potentials of providing a low-cost wireless backhaul service to mobile clients. Many applications in WMNs require efficient and reliable multicast communication, i.e., with high delivery ratio but with less overhead among a group of recipients. However, in spite of its significance, there has been little work on providing such a multicast in mesh networks. Traditional multicasting protocols for wireless multi-hop networks mostly assume that all nodes (equipped with a single interface) collaborate on the same channel. The single-channel assumption is not always true for WMNs that often provide the nodes with multiple interfaces for the purpose of subperformance enhancement. stantial multichannel/interface mesh environments, the same multicast data need to be sent multiple times by a sender node if its neighboring nodes operate on different channels. In this paper, we try to tackle this challenging issue of how to design a multicast protocol more suitable for multiinterface and multi-channel WMNs. Our multicasting protocol builds multicast paths while inviting multicast members, and allocates the same channel to each of neighboring members in a bottom up manner. This mechanism may reduce message overheads and delivery delays while guaranteeing successful message deliveries. For the performance evaluation, we have implemented the proposed scheme on a real multi-channel/interface mesh network test-bed with two IEEE 802.11a cards per node.

I. INTRODUCTION

Multi-Channel Multi-Interface (MCMI) wireless mesh networks have been emerging as a new paradigm in multi-hop wireless networks. They enhance network-wise throughput by highly parallelizing packet forwarding, which is limited in single channel networks. In MCMI WMNs, neighboring nodes try not to share occupying channel to maximize simultaneous packet transmissions; when two neighboring nodes occupy the same channel, only either of them communicates at a time. We call this

policy as the *maximized channel distribution*. Wireless communications are known to have advantages in multicasts of having open communication media, *air*, shared by all nodes within a communication range as long as the nodes are tuned to the channel. However, notice that such an advantage will be gone with the maximized channel distribution. Especially, if the dominant communications in a network is multicast like in, military command networks, the maximized channel distribution may be even harmful.

To cope with this problem, recent researches have proposed top-down and centralized multicasting schemes initiated by the group owner (source node) [1,5,6]. Here, the source node of a multicast group builds a minimal path tree from the source (root) to all group members (leafs). Then, it enforces to assign the same channel on all child nodes under a one-hop parent (sender). However, this top-down enforcement can break the balance of other communications and a centralized approach increases control message overheads. We instead take a bottom-up and distributed approach to construct multicasting tree and to assign channels. Bottom-up approach scales up better at the network environment where various communications co-exist, and requires less control overheads.

On the other hand, previous researches are mostly focused on building of minimal path tree from the source node to multicast client nodes, and do not provide the entire practical procedure of multicasting (e.g., session creation/close and advertisement, member management, etc.). Moreover, they are not implemented on real environments but only evaluated on simulation tools.

Our multicasting protocol builds multicast paths while inviting multicast members, and allocates same channel to each of neighboring members in a bottom up manner. While building paths, intermediate relaying nodes are minimally employed not only by path length but also by current link quality. We have implemented our multicasting protocol with the real MCMI test beds, Net-X [3]. We have shown that our scheme can reduce message overheads and delivery delays while guaranteeing successful message deliveries by performance evaluations.

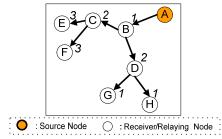

Fig. 1. An example of hidden terminal problem on a multicast tree constructed by MCM algorithm

II. RELATED WORKS

Though multicasting can be an effective routing service. there are not much works on multicasting for MCMI WMNs. In [1], the most closely related work to ours, Zeng et al. proposed a multi-channel multicast (MCM) scheme which consists of a sub-optimal multicast tree construction algorithm and a channel allocation algorithm. At first, they find out the minimal set of relaying nodes after BFS (breadth first search), and build the tree which spans every member node of the multicast group from the source node. After then, they assign the identical channel on sibling nodes that have the same parent on the tree. This strategy can minimize the number of links from a source to all group members with small co-channel interference. Cheng et al. proposed a greedy algorithm to minimize total channel conflicts (the number of interfering links) and the tree cost [6]. Their algorithm randomly creates a sub-route from the source to any receiver node, and assigns channels on all nodes in the route. It repeats this procedure until the desired sub-optimal total channel conflict value is reached, while selecting the route that has less total channel con*flicts* at every iteration.

Nguyen et al. proposed a new channel assignment scheme that can reduce channel conflicts by relieving hidden channel problem, from which MCM algorithm [1] may suffer [5]. The hidden channel problem, which is similar to hidden terminal problem in MANET, occurs when two remote nodes (i.e., two-hops away from each other) try to tune on the same channel. Fig.2 shows an example of the hidden channel problem when a multicast tree is constructed and receiving channels of all nodes are assigned by MCM algorithm. We assume that the numbers written close by the node figures are the assigned channels of each node. Multicast data are transmitted from node A (source) to all nodes by multi-hop only on each of their one-hop child's channels (e.g., node B sends out packets only on channel 2). As both node B and G are tuned on channel 1 for receiving, both node A and D will transmit packets on channel 1. Then, the signals sent from both node A and D will conflict with each other at node B if they transmit at the same time.

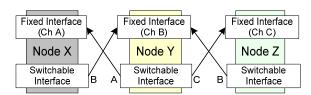

Fig. 2 A simple illustration of our network model (3 nodes, each of which has 2 wireless interfaces)

Therefore, node B may not receive correct multicast packets from node A. To reduce these channel conflicts, Nguyen et al. employs not only orthogonal channels but also partially overlapped channels for the channel assignment. To reduce the adjacent channel interference caused by employing partially overlapped channels, they also proposed a sub-optimal channel separation algorithm by considering interference between all channels.

As pointed out earlier, these previous schemes for MCMI WMNs employ a top-down and centralized method. Thus, building multicast trees and assigning distinct channels on every node require the source (or centric) node to know all the information about network topology immediately and to exchange control message with every node. Moreover, some channel assignment forced by source node may conflict with the current channel assignment strategy in the target WMN. For example, Net-X one of MCMI WMNs employs balanced channel allocation strategy, which tries to tune distinct channels on every node within two-hop range to decrease co-channel interference for the unicast transmission [2]. Therefore, we suggest a bottom-up and distributed based multicasting scheme that also considers current link quality.

III. NETWORK MODEL

Our MCMI WMN model, similar to the one used in [2,3,7], consists of several wireless mesh nodes each of which is equipped with two wireless interfaces. One of these interfaces used only for receiving data is referred to as Fixed Interface and the channel tuned on the fixed interface is called Fixed Channel. A node can receive data only on its fixed channel. The other interface is named Switchable Interface. If a node wants to transmit data to another node, it tunes its switchable interface to the fixed channel of the destination node before transmitting the data. Of course, if two neighboring nodes share the same fixed channel, then the transmitter sends data on its fixed interface. Fig.2 shows an example of data communication in our network model assuming that there are three nodes (Node X, Y, Z) and the fixed channel of each node is A, B, and C, respectively. However, if Node Z is using channel B as the fixed channel instead of channel C, then Node B will use its fixed interface for data transmission to Node Z.

Nodes exchange their fixed channel information by periodically broadcasting "Hello Messages" on all possible channels. By exchanging hello messages, every node can also check current link quality from each of its neighbors. Each node keeps a tab of the successfully received hello messages in last 64*H seconds where H is the hello interval while maintaining 64-bitmaps for each of its neighboring node. A node can estimate the link quality between another node by using both backward and forward link delivery probability. Backward link delivery probability for a neighboring node can be estimated by this mechanism. By enclosing each of these estimated values of all neighbors while sending hello message, every node comes to know the forward link delivery probability for each of its neighboring nodes. Every node also includes its neighbor list, fixed channel of each neighbor, and link quality between them in the hello message. Therefore, every node is able to have current information about its one-hop and two-hop neighbors. To reduce co-channel interference, our network system employs a balanced channel algorithm [2] in which the fixed channel of a node may be changed over time if there are many neighboring nodes in two-hop ranges who are using the same fixed channel.

Like other MCMI WMNs, the same broadcast data need to be sent multiple times by a sender on all possible channels. For multicasting, the source node disseminates multicast data only on the channels that are written in the multicast table. Channels and interface information are filled in the multicast table with respect to multicast groups.

We denote G=(V,E) to a network graph where V represents a node and E represents a unidirectional direct link among nodes. If $u, v \in V$, and a unidirectional direct link $(u, v) \in E$ exists, then node u can transmit data to node v directly without through other nodes. We define Q(u,v) as a delivery probability from u to v when $(u,v) \in E$ exists, which ranges from 0 to 1. The term delivery probability and link quality will be used interchangeably with the same meaning in this paper. We can estimate current link quality by exploiting received hello messages without extra network overhead. We define Th_{mci} as a minimal delivery probability for a reliable direct link in multicast session n. If $Q(u,v) \ge Th_{MCn}$, and $Q(u,v) \ge Th_{MCn}$ where $u, v \in V$ and $(u, v) \in E$ exists, then we say that node u and v is a one-hop neighbor of each other in multicast session n. Th_{MCn} value may be proportional to the required minimal success ratio of data delivery for the multicasting session n. In this paper, we also use the term multicast session and multicast group interchangeably with the same meaning.

Table 1. Major messages for the multicasting

Message	Featured Contents	Description
JOIN_ADV	List of next relaying nodes	Broadcast message originated by source node to advertise the session.
JOIN_REQ	The address of the node originated this message	Unicast message sent by a node who wants to join the session.
JOIN_RPL	the channel adjusting information for switching target	Unicast message sent by a source or a relaying node on response to JOIN_REQ
MCAST _DATA	Data	Multicast data originated by the source node

IV. MULTICASTING FOR MULTI-CHANNEL MULTI-INTERFACE WMNS

A source node initiates a multicast group and disseminates an advertisement message to every node in the network. This message is supposed to be relayed only by some designated intermediate nodes, which are chosen among the current sender's one-hop neighbors. A multicast tree is constructed while the advertisement message is being disseminated hop by hop. Thus, on receiving the advertisement message and attempting to join the group, a node replies a join message back to the node (parent node) that has sent the advertisement message to itself. Now, when receiving the join message, the node sets the sender node as one of its child nodes and sends a reply message to that node. Some channel adjustment information is enclosed in the reply message to let newly joined child node have the same fixed channel as other child nodes have. When the source node sends multicast data, it is relayed to all group member nodes only through designated relaying nodes. Table 1 describes major control and data messages for our multicasting scheme. Every multicast message includes multicast session ID, source address, and sender's address by default.

For the relaying of MCAST_DATA to receiver nodes, intermediate nodes can participate in the multicast session as one of following states.

- Coordinator Candidate: A node becomes this state if its IP address matches one of relaying node addresses enclosed in the received JOIN ADV.
- Multichannel Coordinator: An intermediate node who relays MCAST_DATA. Only a Coordinator Candidate node can become this state after receiving JOIN REQ.

Algorithm 1. Link-quality based minimal relaying node search algorithm

INPUT: p_{ij} : the parent node of node uN1,; a set of u's all 1-hop neighbors N2,; a set of u's all 2-hop neighbors **OUTPUT:** MPR_u: the set of relay nodes from node u $N1_u = N1_u - \{p_u\}$; // exclude p_u $N1_{u} = N1_{u} - N1_{n}$; // exclude p_{u} 's one-hop neighbor WHILE (N1_u is not empty && N2_u is not empty) DO Find a set S_k where $S_k \subset N2_u$ and every element k_i of S_k has the smallest size of parent set $P_k = N1_k \cap N1_u$ among all elements in N2,; $S_{P_k} = \bigcup_{k_i}^{S_k} P_{k_i}$ where $\forall k_i \in S_k$; Find a set S_l where $S_l \subset S_{P_k}$ and every element I_i of S_l has the largest size of the child set $C_{I_i} = N1_{I_i} \cap N2_u$; $l_{\max} = \left\{ l_i \middle| \max_{\forall l_i \in S_i \text{ where } i = 1 \text{ to} \mid S_i \mid} \{ Q(u, l_i) \} \text{ and } Q(l_i, u) \geq Th_{MCn} \right\};$ $MPR_u = MPR_u U \{I_{max}\};$ $N2_u = N2_u - N1_L$; $N1_u = N1_u - \{I_{max}\};$

4.1 Group Management and Channel Adjustment

4.1.1 Join Advertisement and Relaying Procedure

DONE

After a source node initiates a multicast group, it disseminates JOIN_ADV on its all possible channels to advertise the multicast session. The source node finds out the minimal set of relaying nodes among its one-hop neighbors that can span all of its two-hop neighbors, by using the minimal relaying node search algorithm. Then, the set (list) is enclosed in the JOIN_ADV message. Only the nodes in the list forward the message.

A link-quality based minimal relaying set searching algorithm is described in Alg.1. Because finding out the minimal relaying set is a variation of the set-cover problem, which is NP-complete, we have employed the approximate algorithms proposed in [1,8], and modified it by adding a link quality checking procedure. Main idea is as follows: At first, the algorithm finds two-hop neighbors who have the smallest number of parent nodes (i.e., onehop neighbors of current sending node). Then, every parent (i.e., a one-hop neighbor of current node) of these nodes is set as one of relay candidates. At second, among the candidates, the algorithm finds a set of nodes who have the smallest number of child nodes. At third, among the chosen nodes, the algorithm finally finds a relaying node (one-hop neighbor) who has the best link-quality from the current sending node. Then, the node and its child nodes are removed in the one-hop list and the twohop list, respectively. These procedures are repeated until either one-hop neighbor list or two-hop neighbor list become empty.

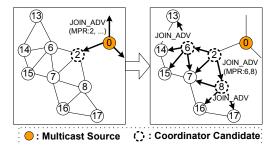

Fig. 3. An example of JOIN_ADV messaging

On receiving JOIN_ADV, the node stores the last sender's address in its parent candidate list for the multicast session. Actually, a node can receive JOIN_ADV for a session more than once because the source node may have sent out the message several times or there can be multiple relaying nodes in physical one-hop range. A node is set to *a coordinator candidate* sate only if its address matches one of relaying node list enclosed in the message. The *coordinator candidate* node overwrites next relaying node list in the message by employing the algorithm, and sends it out on its every possible channel.

Fig.3 shows an example of the procedure for JOIN_ADV originated by a source node (node 0). Node 0 disseminates JOIN_ADV with a relaying node list including node 2. On receiving the message, node 2 becomes a coordinator candidate and forwards the message with new relaying node list (node 6 and node 8). On receiving the message, only node 2 and node 8 become coordinator candidates and forward it. Because the relaying of the message is not needed anymore, node 6 and node 8 sends out the message with empty relaying list, respectively. In that example, node 7 will store node 2, node 6 and node 8 in its parent candidate list for the multicast session.

4.1.2 Member Joining and Channel Adjustment

After receiving JOIN_ADV, if the node wants to join the group, it selects its parent among parent candidate list. A node who currently shows best link quality from this node becomes the parent. We denote a node by u, and the parent candidate set of node u by P_u , the current link quality from x to y by Q(x,y), and all elements of P_u by $v_1, v_2,...v_{|Pu|}$. Then, we can find out the parent node p as Eq.1. Upon the parent has been chosen, the node sends JOIN_REQ to the parent node by unicasting.

$$p = \left\{ v_i \mid \max_{\forall v_i \in P_u \text{ where } i=1 \text{ to} \mid P_u \mid} \{ Q(v_i, u) \} \text{ and } Q(u, v_i) \ge Th_{MCn} \right\}$$
 (1)

On receiving JOIN_ REQ, if the node is in *coordinator* candidate state, then it reports the information to its parent that is also selected from its parent candidate list using Eq.1. Then, the node changes its state to *multichannel* cooperator, and stores the requesting node's address in its child list.

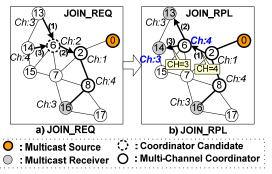

Fig. 4. Member joining and channel adjustment

Algorithm 2. Decision of channel adjustment information

INPUT: *curr*: current parent node, *req*: join requesting node

CH_{curr}: Fixed channel of node *curr*CH_{req}: Fixed channel of node *req*C_List_{curr}: child list of node *curr*CH_List_{curr}: channel list of node *curr*

DONE

OUTPUT: CH_{ADJ}: Fixed channel to be stored in the channel adjustment information

IF $(C_List_{curr}$ is empty)
IF $(CH_{req} == CH_{curr})$ $CH_{ADJ} =$ one of channels in CH_List_{curr} except CH_{req} ELSE $CH_{ADJ} = CH_{req}$ ELSE $CH_{ADJ} =$ the dominant fixed channel used in C_List_{curr}

On responding to JOIN REQ, the node sends JOIN RPL to the requesting node. For the efficient multicasting, the channel adjustment is performed by a coordinator candidate or multichannel coordinator node. The channel adjusting information (new fixed channel of the child node) is determined by the channel adjustment algorithm as shown in Alg.2, and enclosed in JOIN REQ. If the node who has sent JOIN REQ is the first coming child of current node (parent), then the adjustment information is set to as the child's current fixed channel unless the fixed channel is same to its parent's. If the fixed channels are same, the parent node selects other one from its channel list to avoid channel conflict. If the node who has sent JOIN REQ is not the first coming child, then the channel information in JOIN RPL will be set as a dominant fixed channel that most of nodes in the child list of the parent node are using. On receiving JOIN RPL, the node changes its fixed channel on according to the channel adjustment information in the message, and locks its fixed channel not to change during the multicast session.

Fig.4 shows an example of member joining and channel adjustment procedure when node 13 and node 14 try to join the multicast group. "Ch:x" written by a node means its current fixed channel, the number by a link is the logical sequence of message events. In Fig.4(a), node 13 sends JOIN_REQ to node 6. Because node 6 is still in *coordinator candidate* state and the child list is empty, it forwards the message to node 2 who is its parent.

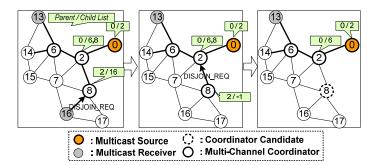

Fig.5. Member disjoining procedure

In that moment, node 14 sends JOIN_REQ to node 6. In Fig.4(b), after then, node 2 sends JOIN_RPL with channel adjusting information (CH=4) to node 6 because it already has node 8 as a child whose fixed channel is 4. Then, node 6 switchs its fixed channel to channel 4, and sends JOIN_RPL to node 14 with channel adjusting information (CH=3) to make node 14 switch its fixed channel to channel 3 that is being used by node 13.

4.1.3 Member Disjoin

A receiver node sends DISJOIN_REQ message to its current parent. After sending DISJOIN_REQ, the node unlocks its channel lock and removes all relevant data structures. On receiving DISJOIN_REQ from its child, the *multichannel coordinator* node removes the node in its child list. If a *multichannel coordinator* node's child list becomes empty, then it sends DISJOIN_REQ to its parent node, resigns from *multichannel coordinator* state, and releases all relevant data. Fig.5 shows an example of member disjoining procedure when node 16 is about to disjoin the group. Node 16 sends DISJOIN_REQ to node 8 who is its parent and a multichannel coordinator. Because the child list of node 8 became empty, node 8 sends DISJOIN_REQ to node 2 who is its parent. Finally, node 2 removes node 8 from its child list.

4.2 Multicast Data Forwarding

The source node sends out MCAST_DATA only on the channel that its one-hop child nodes are listening on. On receiving the data, only multichannel coordinators forward them in the same manner. With these sophisticated procedures, message overheads can be minimized.

4.3. Managing of Reliable Multicasting

We also address the side effects of channel assignment in multicast group initialization. In practical MCMI WMNs, a so-called *link fluctuation problem* caused by the fluctuating link quality may seriously degrade the reliability of multicasting. In Fig.6(a), the wireless link from node 0 to node 3 is considered as a one-hop route for a multicasting session while initializing the group. We assume that node 0 is a source and node 3 is a client for a multicast session.

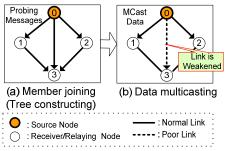

Fig. 6. Link fluctuation problem

If node 3 receives a child-probing message from node 0 for constructing a multicast tree, then node 3 may set node 0 as its one-hop parent. Then, node 3 will receive multicast data from node 0 neither node 1 nor 2. However, if the link quality between node 0 and 3 becomes too low by some reasons, then most of the multicast data sent by node 0 will not be delivered to node 3 as shown in Fig.6(b).

Dynamic channel allocation used in MCMI WMNs may be one of the major reasons of the link fluctuation. Although we usually assume that every channel has equal link quality, it may not be true in practice because physical characteristics of each channel are various. By device specific characteristics, some channels may have stronger signal power or higher tolerance against specific interferences than other channels [11]. That is to say, a wireless link between two neighboring nodes may be disconnected or weakened after changing their operating channels. To cope with these problems, we let every member node keeps not one parent but several parent candidates for a multicast tree during tree construction. After then, the node will receive multicast data from the chosen parent node in the candidate list who has the best link quality between the node.

V. IMPLEMENTATION AND EVALUATION

5.1 Experimental Environments

Our MCMI WMN test-bed consists of 18 Soekris net4521 nodes deployed on the 4th floor of CSL building in University of Illinois. Fig.7 shows a screen shot of our monitoring tool displaying current state of deployed nodes. Each node has a 133MHz CPU and two Atheros 802.11a interfaces as a fixed and switchable interface. We implemented our multicasting scheme on top of IEEE 802.11a protocol and Linux 2.4.6 kernel. Though 802.11a has 12 orthogonal channels in 5 GHz band, we use four concurrent channels (i.e., 40, 52, 64, and 149) to avoid adjacent channel interferences. We set the wireless interfaces to operate at 6Mbps fixed mode. Slightly modified Madwifi driver is used for the wireless device driver. The two interfaces are abstracted as one by using bonding driver. Fundamental software architecture is borrowed from Net-X system [3] and modified.

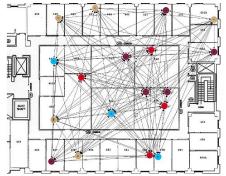

Fig. 7. Deployed nodes for the experiments

We evaluate the performance of our proposed algorithm (MMCA) by comparing to MMNCA and SCM. Each is described as follows:

- Single Channel based Multicasting (SCM): MCAST_DATA originated by a source node are forwarded only by the chosen intermediate nodes (relay nodes) in the multi-hop environment. These relay nodes are determined by minimal multiple relaying algorithms. Data transmission in the relaying or source node is done by broadcasting on every channel the node has.
- MCMI-based Multicasting with no Channel Adjustment (MMNCA): Determining of relay nodes and relaying of MCAST_DATA are same to those of SCM. Multicast data from the relaying or source node are sent out only on the channels being used by one-hop neighbors who are multicast receivers or relay nodes.
- MCMI-based Multicasting with Channel Adjustment (MMCA): Determining of relay nodes and relaying/transmitting of MCAST_DATA are same to those of MMNCA. The relaying or source node tries to unifying fixed channels of its one-hop child nodes by sending JOIN RPL with channel adjusting information to them.

Performance metrics for our evaluation are as follows:

- **Network traffic:** sum of multicast traffic every node sends during an experiment
- **Delivery ratio:** the average ratio of successful delivery of MCAST_DATA each multicasting receiver receives during an experiment
- Average goodput: the average amount of nonredundant MCAST_DATA each multicasting receiver receives during an experiment.

5.2 Results and Analysis

We assume that the number of multicast group and its source node is one. The size of a MCAST_DATA packet is 1024 bytes. Hello messages are disseminated by every node at every 4 seconds. The minimal link quality for a reliable direct link (Th_{mci}) is set to 0.96. Experiments for each scenario are repeated by 30 times.

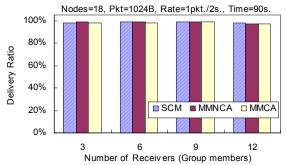

Fig. 8 Data delivery success ratio

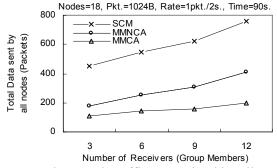

Fig. 9. Total network traffic transmitted by all nodes

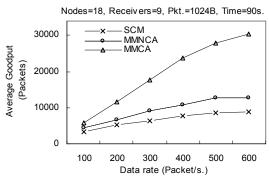

Fig. 10. Average goodput per receiver

the Fig.8 shows delivery success ratio for MCAST DATA packets sent by the source node by varying number of multicast receivers (group members) during 90 seconds. As we can see the results, our scheme (MMCA) shows similar delivery success ratio comparing with others. We also measured total network traffic sent by all nodes for the multicast. Total 46080 bytes of MCAST DATA are sent out from the source node. As we can see in Fig.9, channel adjustment of MMCA can effectively reduces network traffic overheads comparing to other schemes.

We have measured the goodput of each scheme during 90 seconds by varying the MCAST_DATA transmission rate from 100 packets/sec to 500 packets/sec when receivers are 9. As we can see in Fig.10, MMCA shows more than double times of goodput than other schemes over 400 packet/sec. Delays for switching channels on the switcha-

ble interface to send out data on all possible channels may incur buffer overflow which decreases goodput in SCM. Moreover, broadcasting on all possible channels may incur co-channel interference to MCAST_DATA transmissions of near nodes. MMNCA may also be suffered from the same problem if relaying or source nodes have more than one child.

VI. CONCLUSION

In this paper, we try to tackle several challenging issues of designing a multicast protocol more suitable for MCMI WMNs. Our multicasting protocol builds multicast paths while inviting multicast members, and allocates same channel to each of neighboring members with bottom upbased and distributed-oriented approaches. This mechanism reduces message overheads and delivery delays while guaranteeing successful message deliveries. We have implemented the proposed scheme on a real multichannel mesh network testbed (Net-X), and have shown that our proposed scheme performed better than previous ones without reliability degradation.
